MMWR
MORBIDITY AND MORTALITY WEEKLY REPORT

Epidemiologic Notes and Reports

Fatalities Attributed to Entering Manure Waste Pits — Minnesota, 1992

In August 1992, four farm workers in Minnesota died in two separate incidents after entering manure waste pits: two were poisoned by hydrogen sulfide gas, and two were asphyxiated. The Minnesota Fatality Assessment and Control Evaluation (FACE) program was notified of the incidents by the state Occupational Safety and Health Administration and the Minnesota Farming Health Project, respectively. This report summarizes the investigations of these two incidents by the Minnesota FACE program and CDC's National Institute for Occupational Safety and Health (NIOSH) FACE personnel.

Incident 1

On August 8, a 27-year-old employee of a hog farm and his 46-year-old uncle, who co-owned the farm, died after entering an outdoor manure pit. On August 7, the farm employee and a coworker had attempted to pump out the 12-foot-deep, 49-inch-diameter pit but could not because of a clogged pump intake in the pit. When they attempted to extract the pump from the pit with an attached ¼-inch wire rope, the rope broke. The following morning, although cautioned by his coworker about the possible presence of poisonous gases in the manure pit, the employee indicated he had entered the pit in the past without trouble and descended a ladder 9 feet into the pit to attach a new rope to the pump. While attempting to attach the rope, he was overcome and fell off the ladder into the pit. The coworker summoned rescue personnel and the farm co-owner.

Although the co-owner also was warned of possible poisonous gases in the pit, and despite efforts to physically restrain him, he descended the ladder into the pit 10 minutes after the nephew had entered; he also was overcome and fell into the pit. Twenty minutes after the initial entry, both men were removed from the pit by rescue personnel equipped with appropriate respiratory protection (self-contained breathing apparatus). Cardiopulmonary resuscitation was initiated, and the men were transported to a hospital where both were pronounced dead on arrival. The death certificates listed hydrogen sulfide poisoning as the cause of death for both men.

Manure Waste Pits — Continued

Atmospheric readings in the pit on September 2 during the FACE investigation detected no measurable levels of hydrogen sulfide or methane and an oxygen level of 20.4% (normal: 19.5%–21.0%). However, the weather conditions on the day the readings were taken (cool and breezy) differed from those on the day of the incident (hot and humid).

Incident 2

On August 11, a 43-year-old dairy farm owner and his 23-year-old son died from asphyxiation after entering one of two adjacent manure waste pits underneath a barn. The 8-foot-deep pits were connected by a tunnel so that both could be pumped from one pit. Although the incident was unwitnessed, an investigation of physical evidence and interviews with rescue personnel suggested the following series of events: The two men were using a pump located outside the barn to pump manure from the pits into the tank of a manure spreader. They pumped the manure from the first pit but apparently were unable to pump manure from the adjacent pit because of an obstruction in the connecting tunnel. The father then removed a steel grate cover, descended a ladder into the nearly empty pit, and was overcome as he began to clear the tunnel obstruction. His son was found lying on top of him, apparently overcome during a rescue attempt. The men were discovered approximately 2½ hours later, based on the coroner's estimated time of death for the men.

The men were removed from the manure pit by rescue personnel equipped with appropriate respiratory protection and were pronounced dead at the scene by the coroner. The coroner attributed the cause of death for both men to asphyxiation due to hypoxia.

Reported by: G Madery, MS, D Parker, MD, Section of Chronic Disease and Environmental Epidemiology, Minnesota Dept of Health; J Shutske, PhD, Dept of Agricultural Engineering, Univ of Minnesota, St. Paul. Div of Safety Research, National Institute for Occupational Safety and Health, CDC.

Editorial Note: A manure waste pit, by its design, meets the criteria established by NIOSH for a confined space (i.e., a space with limited openings for entry and exit, with unfavorable natural ventilation that could contain or produce dangerous air contaminants, and that is not intended for continuous worker occupancy [*1*]). The fermentation and decomposition of waste can create oxygen-deficient, toxic, and/or explosive atmospheres; the anaerobic bacterial action that decomposes the manure can generate methane, hydrogen sulfide, carbon dioxide, and ammonia. Death can result either from oxygen deficiency or from the direct toxic effects of these gases (*2*).

Sources of data to study work-related confined space fatalities, such as those described in this report, include the FACE program and the National Traumatic Occupational Fatality (NTOF) surveillance system. The FACE program collects epidemiologic data from the investigation of selected occupational fatalities, identifies factors that might increase the risk for work-related fatal injury, and develops and disseminates preventive recommendations to address these risks. Minnesota is one of 12 states* that receive funding from NIOSH for state FACE programs. NIOSH's Division of Safety Research monitors overall numbers of acute traumatic occupational deaths in the United States using the NTOF surveillance system, a census of fatal

*Alaska, California, Colorado, Georgia, Indiana, Iowa, Massachusetts, Minnesota, Missouri, New Jersey, Wisconsin, and Wyoming.

Manure Waste Pits — Continued

work-related injuries based on death certificate information collected from the 52 U.S. vital statistics reporting units[†] (*3*).

As described in this report, incidents involving entry into confined spaces often result in multiple fatalities when coworkers or others die during attempts to rescue initial victims; on farms these are often family members. For 1980–1989, the NTOF surveillance system identified a yearly average of 89 occupational deaths that occurred in any type of confined space. Of these, approximately 20 (22%) occurred each year during rescue attempts (*3*). Similarly, from 1982 through 1992, as part of the FACE program, NIOSH personnel investigated 68 confined-space incidents that resulted in 104 fatalities; of these, 36 (35%) were workers who died during rescue attempts (*4*), and two were public safety personnel. Persons who died during rescue attempts were more likely to be coworkers than public safety or emergency medical service (EMS) personnel (*5*). Asphyxiation by atmospheric hazards was the primary cause of rescuer death, although the exact mechanism of death is often difficult to determine. In general, findings of autopsies performed on manure pit fatality victims are nonspecific and do not identify the specific gas(es) likely to have caused death.

Rescue operations in confined spaces present unique hazards, and proper training and specialized equipment are required to protect rescuers from injury and death. Public safety and EMS personnel should be able to recognize confined-space hazards and should be familiar with the use of proper rescue equipment and techniques (*1,6–8*).

In the two incidents described in this report and in similar incidents investigated by NIOSH (*9,10*), hot, humid weather may have contributed to the generation of gases in the manure pits, an association also suggested by NTOF data (Figure 1). The 22 deaths during 1980–1989 identified by NTOF data[§] that were attributed to asphyxiation of workers in manure pits or similar waste tanks occurred in 13 states[¶] during April through September. Although manure pit gases are potentially present at all times, farm workers should be particularly aware of the hazards of entering manure pits during summer months, when conditions are optimal for the microbial activity that can result in increased gas generation. Manure pits that have previously been entered without incident may become toxic and/or oxygen deficient, and this change would not be detected without testing the atmosphere of the pit.

To prevent serious or fatal exposures such as those described in this report, NIOSH recommends that manure waste pits be identified as confined spaces and that warning signs be posted at all entrances to these pits. Farm workers should be instructed never to enter manure waste pits, even to attempt a rescue, unless appropriate safety measures are employed; these include the use of appropriate respiratory protection and adherence to safe confined-space entry procedures. In addition, where possible, manure waste systems should be designed to provide access to all serviceable parts from outside the pit. Manufacturers of equipment designed for use in manure waste

[†]The 50 states, Washington, D.C., and New York City.

[§]Because NTOF data include only deaths of workers aged ≥16 years that are clearly identified as being work related and because death certificates often do not include sufficient information to identify specifically deaths occurring in manure pits, this enumeration may underestimate asphyxiation fatalities that occurred during this period among those working in manure pits.

Current Trends

Update: Investigations of Persons Treated by HIV-Infected Health-Care Workers — United States

Previous reports have described transmission of human immunodeficiency virus (HIV) to five persons (patients A, B, C, E, and G) during receipt of care from an HIV-infected dentist in Florida (*1–3*) and other investigations of patients who were treated by HIV-infected health-care workers (HCWs) (*4*). This report updates these investigations and presents evidence that a sixth patient (patient I) became infected with HIV while receiving care at the Florida dental practice, the only practice in which HIV transmission from an infected HCW to patients has been documented.

Investigation of Patients of HIV-Infected HCWs (Excludes Florida Dental Practice)

As of March 31, 1993, HIV tests were completed for 19,036 persons treated by 57 HIV-infected HCWs. These results include findings in published reports (*4–7*) and unpublished investigations reported to CDC.

No seropositive persons were reported among 11,529 patients tested from the practices of 46 HCWs, including 23 dentists and dental students, 12 physicians and medical students, seven surgeons and obstetricians, and four others. For the remaining 11 HCWs (six dentists and five surgeons and obstetricians), 7507 patients were tested, and 92 seropositive patients were identified. Follow-up investigations have been completed for 86 (94%) of these 92 patients: eight patients were documented to be infected before receiving care from the HIV-infected HCW; 54 had established risk factors for HIV; 19 may have had other opportunities for exposure to HIV (i.e., exchange of sex for drugs or money and/or multiple sex partners); and five had no risks identified. Investigations are in progress for six patients of two HCWs.

Genetic sequencing was performed on HIV strains from 29 of the 92 seropositive patients from the practices of three HCWs. Eleven of these 29 had established risks, 15 had other opportunities for exposure to HIV, and three had no identified risk. Sequencing was not performed on the isolates for the remaining two of the five patients with no identified risk because one patient died before a blood sample could be collected, and the other refused to provide a sample. The degree of genetic similarity of viruses from the patients and the infected HCWs was in the range previously reported for persons with epidemiologically unrelated infections (*5,6*; CDC, unpublished data). Thus, follow-up to date has not demonstrated transmission from an HCW as a source of HIV infection for any of the patients tested.

Epidemiologic and Laboratory Investigation of Patient I

Patient I, a teenaged female, was HIV seropositive when tested as an applicant for military service in late 1992. She had not previously been tested for HIV infection, although she was notified in December 1990 by the Florida Department of Health and

HIV Infection — Continued

Rehabilitative Services (HRS) that, as a former patient of the dentist, she should consider such testing.

Multiple interviews with the patient and her family and review of her medical records did not identify another mode of exposure to HIV. She denied previous injecting-drug use, receipt of blood or blood products, a history of sexually transmitted diseases, or sex with persons infected with HIV or at increased risk for HIV infection. She did not recall, nor did review of her medical records reveal, an illness compatible with an acute retroviral illness. Five of her six lifetime sex partners were tested and were negative for HIV antibody. The sixth sex partner, with whom the patient reported a single sexual contact using a condom, has not been located. The patient's CD4+ T-lymphocyte count at the time of HIV diagnosis was 429 cells/μL. Serologic tests for syphilis and hepatitis B were negative.

Interviews with the patient and her parents indicated she was a patient in the dental office during the summers of 1987, 1988, and 1989 for examinations, radiographs, prophylaxes, and restorative fillings under local anesthesia. Her dental records from the practice cannot be located; therefore, whether she shared a visit date with any of the other five infected patients is unknown. An insurance record documented a visit in August 1988 for an examination, radiographs, and prophylaxis. Bitewing radiographs taken in 1990 by another dentist indicate that single surface restorative fillings had been placed in three permanent molars. Before 1987, the patient had received no other dental care since the eruption of her permanent teeth. She did not recall any injury to the dentist or other unusual events during the dental procedures or whether the dentist or the hygienist performed the prophylaxes.

Peripheral blood mononuclear cells were obtained from patient I, and proviral DNA was extracted, amplified, cloned, and sequenced (*2*) to determine the relatedness of the HIV strain from patient I to those of the dentist and patients A, B, C, E, and G. A direct sequence of amplified DNA and nine cloned sequences each included approximately 325 nucleotides of the C2-V3 region of the *env* gene. In addition, six shorter clone sequences were produced. Sequence analyses were performed at Los Alamos National Laboratory and at CDC.

The genetic divergence (i.e., intrapatient nucleotide sequence distances) among the nine complete C2-V3 clones from patient I averaged 3.2% (range: 0.3%–5.0%). The viruses of the dentist and patient I were closely related, with an average genetic divergence of 4.3% (range: 2.8%–7.8%), and the viruses of patient I and patients A, B, C, E, and G also were closely related, with an average divergence of 4.9% (range: 2.1%–8.1%). In comparison, the sequences of patient I were distinct from those of the 34 local controls (*2*), with an average genetic divergence of 12.0% (range: 6.8%–17.9%). Based on direct sequences of 186 nucleotides from the viruses infecting patients A, B, C, E, G, and 28 of the 34 local controls, the HIV strains from patients A, B, C, E, and G were significantly closer in their DNA sequences to patient I's virus than the control patients ($p<0.0001$, Wilcoxon rank sum test).

In addition to the genetic divergence analysis, signature pattern analysis of both amino acids and nucleotides* (*2,8*) and phylogenetic tree analysis (*2*) each independently showed the similarity of patient I's sequences and those of the dentist and patients A, B, C, E, and G. Analyses of the six shorter clone sequences and the direct amplification product from patient I were consistent with this finding.

HIV Infection — Continued

Reported by: JJ Witte, MD, Florida Dept of Health and Rehabilitative Svcs. Los Alamos National Laboratory, New Mexico. Div of HIV/AIDS, and Hospital Infections Program, National Center for Infectious Diseases; Div of Oral Health, National Center for Prevention Svcs; National Institute for Occupational Safety and Health, CDC.

Editorial Note: The results of the epidemiologic and laboratory investigation of patient I indicate that she became infected with HIV while receiving care from an HIV-infected dentist. She had had no other confirmed exposures to HIV. In addition, DNA sequence analysis showed her HIV strain had a high degree of similarity to that of the dentist and the five other infected patients. The precise event(s) resulting in HIV transmission in this practice remain(s) unknown (*1*). Unlike the other five infected patients, patient I had neither dental extractions nor root canal therapy. Opportunities for injuries to the dentist were limited. However, exposure of patient I to the dentist's blood cannot be ruled out (e.g., related to use of the anesthetic syringe).

Approximately 1100 patients of the dentist are known to have been tested for HIV. In late 1990, HRS used available records to compile a partial list of the patients in the dental practice and notified those patients who had not been tested. Former patients who have not yet been tested should contact their local health department or private physician to discuss HIV testing.

Among the 58 investigated practices described in this report, the dental practice in Florida remains the only documented instance of HIV transmission from an HCW to patients. The risk for transmission of a bloodborne pathogen from an HCW to a patient is associated with the circulating titer of the pathogen in blood, the procedures performed, techniques and infection-control precautions used, and the medical condition of the HCW (*9*).

The results presented in this report are consistent with previous assessments that the risk for HIV transmission from an infected HCW to patients during invasive procedures is small and can be reduced with appropriate use of infection-control precautions (*9,10*).

*Patient I's viral C2-V3 amino acid sequences were characterized by a stringently defined signature pattern, A-A-G-E-V-I-H; these seven, atypical amino acid residues were found by computer analysis in each of the nine viral clone sequences consisting of approximately 108 deduced amino acids. The dentist's viral C2-V3 amino acid sequences were characterized by a stringently defined signature of eight noncontiguous residues, A-I-A-G-A-E-V-H, and a majority signature, present in most of the viral clone sequences from the dentist, consisting of 10 noncontiguous residues, A-I-A-G-A-E-E-V-I-H. Of the seven residues in patient I's signature, five were found in the stringently defined dentist signature and all seven were present in the majority signature of the dentist's viruses.

Patient I's stringently defined nucleotide signature pattern consisted of 12 atypical, noncontiguous residues detected in each of the nine viral clone sequences of approximately 325 nucleotides. All 12 of these nucleotides were present in five of the six dentist's clone sequences; 11 of these nucleotides were found in the remaining dentist clone sequence. No sequence from any local control or any other sequence in the HIV Sequence Database contained more than five of these 12 signature nucleotides (most had 1–3). In contrast, all 34 clone sequences from patients A, B, C, E, and G had at least 11 of the signature nucleotides.

Epidemiologic Notes and Reports

Isolation of Wild Poliovirus Type 3 Among Members of a Religious Community Objecting to Vaccination — Alberta, Canada, 1993

During September 1992–February 1993, 68 cases of poliomyelitis occurred among members of a religious community in the Netherlands (*1*). Because members of an affiliated religious community in Alberta, Canada, had direct contact (i.e, travel to and from the Netherlands) with members of the affected community, health authorities in Alberta conducted an investigation during January–February 1993 to determine whether this poliovirus had been imported. This report summarizes the results of this investigation (*2*).

The investigation focused on a small rural community in southern Alberta that reported the only case of poliomyelitis from the province during the last outbreak (11 cases) of poliomyelitis in Canada during 1978 (*3,4*). The community comprises members of a religious group that generally opposes vaccination.

Wild poliovirus type 3 (PV3) was isolated from stool specimens obtained from 21 (47%) of 45 persons (primarily children). Laboratory investigations conducted by the National Center for Enteroviruses in Halifax, including application of molecular techniques in collaboration with laboratories at CDC, determined that this PV3 was virtually identical with the strain that caused the recent outbreak in the Netherlands.

No cases of paralytic poliomyelitis have been identified in Canada since 1988. Provincial epidemiologists in Canada, in collaboration with the Laboratory Center for Disease Control in Ottawa, have enhanced surveillance for cases of acute flaccid paralysis. In addition, poliovirus vaccine has been offered to members of all unvaccinated communities. Studies are under way to determine whether poliovirus is circulating among unvaccinated communities in British Columbia and Ontario.

Wild Poliovirus Type 3 — Continued

Adapted from: Canada Communicable Disease Report *1993;19:57–8. Reported by: Div of Viral and Rickettsial Diseases, National Center for Infectious Diseases; Div of Immunization, National Center for Prevention Svcs, CDC.*

Editorial Note: The findings in this report represent the first documented importation and circulation of any wild poliovirus in the Western Hemisphere since the apparent eradication of wild poliovirus infection in August 1991 (*5*). No cases of paralytic poliomyelitis have been reported from the affected community in Alberta; however, because the clinical:subclinical case ratio for PV3 infection may be as low as 1:1000 (*6*), wild poliovirus can circulate in a population group for several months before paralytic disease occurs. The last outbreak of poliomyelitis in the United States occurred in 1979 when 10 paralytic cases were reported from four states (Iowa, Missouri, Pennsylvania, and Wisconsin). That outbreak originated in the Netherlands in 1978 when poliovirus type 1 spread from the Netherlands to Canada and then to the United States (*3,4,7,8*).

In each of these outbreaks, clinical cases of poliomyelitis and asymptomatic infections occurred almost exclusively among religious groups objecting to vaccination. Subgroups of susceptible persons residing within otherwise highly vaccinated general populations can periodically support epidemic transmission of poliomyelitis (*3,4,7,8*). However, the risk for exposure, infection, and paralytic disease among vaccinated persons in the general population is low. Therefore, persons fully vaccinated with poliovirus vaccine (i.e., three to four doses of vaccine) are not considered at increased risk for poliomyelitis, and special efforts (i.e., additional vaccination) are not recommended.

Because of the risk for importation and spread of poliovirus, all persons aged <18 years who are not fully vaccinated should initiate or complete the primary series of poliovirus vaccine according to the recommendations of the Advisory Committee on Immunization Practices (*9,10*). In addition, special efforts are necessary to increase acceptance rates of vaccination and to provide poliovirus vaccines to unvaccinated or incompletely vaccinated members of religious groups who do not generally accept vaccination. Oral poliovirus vaccine (OPV) is recommended for all unvaccinated persons residing in these communities, including those aged ≥18 years, because of its ability to limit community spread if poliovirus is introduced.

Because of the outbreak in the Netherlands and detection of PV3 in Alberta, surveillance of poliomyelitis in the United States has been augmented to include clinical and laboratory investigations of any case of acute paralysis or aseptic meningitis occurring among members of religious groups objecting to vaccination, as well as unvaccinated persons in the general population residing in the vicinity of these religious groups. In addition, studies are under way to document the presence or absence of wild poliovirus in the United States among communities that do not accept vaccination.

The documentation of imported wild poliovirus in Alberta—following a period of 18 months during which wild poliovirus was absent in the Americas—demonstrates the potential for reintroduction of poliovirus into areas where poliomyelitis was considered eliminated. Persons belonging to religious communities objecting to vaccination are currently at greatest risk for paralytic poliomyelitis in the United States. Although efforts are ongoing to protect these communities, the effectiveness of previous vaccination efforts in these communities has been limited. Only global

Wild Poliovirus Type 3 — Continued

eradication of poliomyelitis—a health goal for the year 2000 adopted by the World Health Assembly in 1988—will ensure that poliovirus infection will not cause paralytic disease in the United States or the rest of the world.

Health Objectives for the Nation

Fetal Alcohol Syndrome — United States, 1979–1992

Fetal alcohol syndrome (FAS) is characterized by a variety of physical and behavioral traits that result from maternal alcohol consumption during pregnancy. Features of FAS include prenatal or postnatal growth deficiency, abnormal facial features, and central nervous system deficits (*1*). CDC's Birth Defects Monitoring Program (BDMP)—a national program to monitor congenital malformations—has collected data on the incidence of FAS among newborn infants since 1979. This report presents a rate for FAS in the United States using BDMP data from 1979 through 1992.

The BDMP uses hospital discharge data on newborns gathered by the Commission on Professional and Hospital Activities (CPHA). Data from this system include both live and stillborn infants born in participating hospitals since 1970. Since 1979, discharge diagnosis data have been reported to CDC by CPHA using the *International Classification of Diseases, Ninth Revision, Clinical Modification* (ICD-9-CM). Before 1979, the CPHA used ICD-8, which did not include a code used for FAS. During 1992, the BDMP monitored data on approximately 10% of all births, compared with approximately 30% in 1979.

From 1979 through 1992, a total of 1782 FAS cases were reported among 9,057,624 births, a rate of 2.0 per 10,000 births (Figure 1). During 1992, the BDMP identified 67 infants born with FAS, representing a rate of 3.7 per 10,000 births. This rate is an increase of more than threefold that for 1979 (1.0 per 10,000 births).

Reported by: Birth Defects and Genetic Diseases Br, and Developmental Disabilities Br, Div of Birth Defects and Developmental Disabilities, National Center for Environmental Health, CDC.

Fetal Alcohol Syndrome — Continued

Editorial Note: FAS is a leading preventable cause of birth defects and mental retardation in the United States. FAS represents some of the most serious effects of alcohol to the developing fetus. Because FAS has not been reported in the absence of excessive maternal alcohol consumption during pregnancy, this problem can be prevented by the avoidance of alcohol use by women who are pregnant. A national health objective for the year 2000 is to reduce the rate of FAS to no more than 0.12 per 1000 live births (i.e., 1.2 per 10,000 live births) (objective 14.4) (*2*).

FAS is difficult to recognize in newborns for three reasons: 1) facial stigmata of FAS are often subtle; 2) some types of central nervous system deficit in infants are difficult to detect; and 3) the birthweight of some affected infants is normal. Although the BDMP data are derived from diagnoses made by physicians during the neonatal period, and the sensitivity and specificity of the data are unknown, rates derived from BDMP data are likely to underestimate the true incidence of FAS. Incidence rates for FAS based on the BDMP are substantially lower than those based on other studies (*3*). Because neither the sensitivity nor the specificity of the BDMP data are known, it is difficult to interpret the increase in the incidence of FAS reported to the BDMP. The increase may reflect an increase in the recognition and reporting by physicians and/or a true increase in incidence. Studies are under way to evaluate the sensitivity and specificity of the BDMP data.

CDC, in collaboration with private, voluntary organizations, is promoting Alcohol and Other Drug Related Birth Defects Awareness Week, May 9–15, 1993. These organi-

Notices to Readers

National SAFE KIDS Week

National SAFE KIDS Week, May 22–29, focuses on preventing unintentional injury among children. Highlights will include safety events in communities throughout the United States, distribution of safety information by retailers, and national media coverage. The event is sponsored by the National SAFE KIDS campaign, which provides programmatic support to 150 state and local coalitions in 44 states and the District of Columbia. Additional information is available from the National SAFE KIDS Campaign, 111 Michigan Avenue, NW, Washington, DC 20010.

Workshop on Quality-Assurance and Quality-Control Procedures for CD4+ T-Lymphocyte Determinations

The National Laboratory Training Network (NLTN), a cooperative training system of CDC and the Association of State and Territorial Public Health Laboratory Directors, will sponsor 3-day workshops on quality-assurance and quality-control procedures for T-lymphocyte determinations at sites throughout the country during June and July 1993. This workshop is intended for managers, supervisors, and technical staff of flow cytometric immunophenotyping programs who have at least 6 months' experience operating flow cytometers.

The goal of the workshop is to assist participants in integrating recommended procedures for quality assurance and quality control into their flow cytometric immunophenotyping programs for the determination of CD4+ T-lymphocyte levels in human immunodeficiency virus-infected persons. The workshop will include safety issues; specimen collection, shipping, and storage; selection of the reagent panel; sample preparation and erythrocyte lysis and fixation; flow cytometer set-up and

standardization; sample analysis; data reduction; troubleshooting; report preparation; and overall quality-control procedures.

There is a registration fee. Workshop dates, locations, and telephone numbers of contacts are: June 7–9, Brentwood, Tennessee—contact NLTN Southeastern Office, (615) 262-6315; June 23–25, Milwaukee—contact NLTN Midwestern Office, (312) 793-3306; June 29–July 1, North Dartmouth, Massachusetts—contact NLTN New England Office, (617) 522-3700, ext. 153; July 12–14, Denver—contact NLTN Western Office, (303) 691-4708; July 22–24, Seattle—contact NLTN Pacific Office, (510) 540-3991; and July 28–30, Dallas—contact NLTN South Central Office, (504) 568-2081.

Erratum: Vol. 42, No. 12

Two errors appeared in the article, "Methemoglobinemia in an Infant—Wisconsin, 1992." On page 218, the last sentence should read: "Nitrate reacts with the oxygen-carrying protein, hemoglobin, *oxidizing* it to methemoglobin (Figure 1)." In Figure 1, the bottom arrow and the compounds NAD+ and NADH are reversed; the correct figure is printed below.

FIGURE 1. Basic reactions in the development of nitrate-induced methemoglobinemia

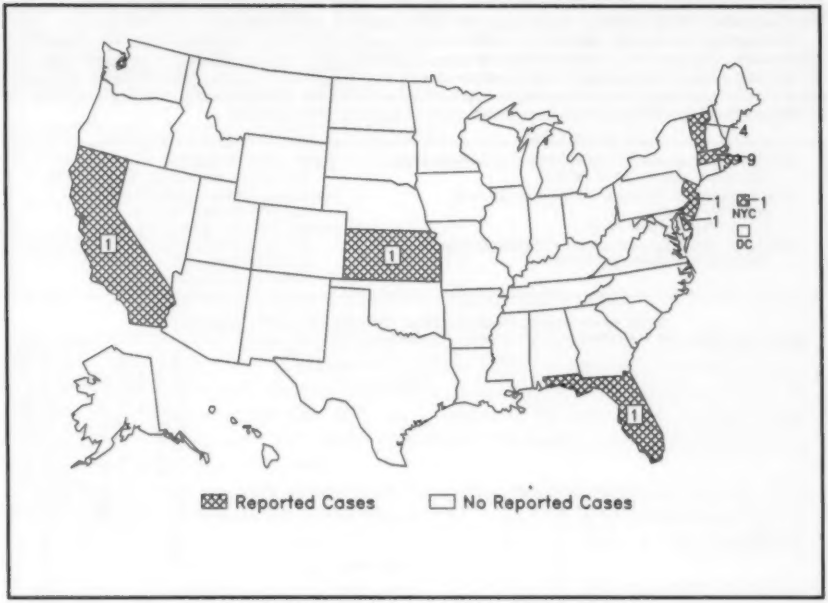
Reported cases of measles, by state — United States, weeks 13–16, 1993



The *Morbidity and Mortality Weekly Report (MMWR)* Series is prepared by the Centers for Disease Control and Prevention (CDC) and is available on a paid subscription basis from the Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402; telephone (202) 783-3238.

The data in the weekly *MMWR* are provisional, based on weekly reports to CDC by state health departments. The reporting week concludes at close of business on Friday; compiled data on a national basis are officially released to the public on the succeeding Friday. Inquiries about the *MMWR* Series, including material to be considered for publication, should be directed to: Editor, *MMWR* Series, Mailstop C-08, Centers for Disease Control and Prevention, Atlanta, GA 30333; telephone (404) 332-4555.
